## Abstract

Digital watermarks have been regarded as a promising way to fight copyright violations in the software industry. In some graph-based watermarking schemes, identification data is disguised as control-flow graphs of dummy code. Recently, Chroni and Nikolopoulos proposed an ingenious such scheme whereby an integer is encoded into a particular kind of permutation graph. We give a formal characterization of the class of graphs generated by their encoding function, which we call canonical reducible permutation graphs. A linear-time recognition algorithm is also given, setting the basis for a polynomial-time algorithm to restore watermarks that underwent the malicious removal of some edges. Finally, we give a simpler decoding algorithm for Chroni and Nikolopoulos' watermarks.

of unlicensed software put into the world market every year exceeds 60 billion dollars [3]. To counter such practice, many promising methods have been devised, among which the idea of software watermarking.

The use of paper watermarks to prevent counterfeiting dates back to the thirteenth century. Generally speaking, watermarks are unique identifiers embedded into proprietary objects to enforce authenticity. In a digital object, particularly in a piece of software, a watermark may act not only as a certificate of authorship, but also as a means of tracing the original owner of the object, therefore discouraging piracy.

The first software watermark was proposed in 1996 by Davidson and Myrsvold [14], while the first watermarking scheme to exploit concepts of Graph Theory was formulated by Venkatesan, Vazirani and Sinha [23] in 2001. Their technique, whereby an integer was encoded as a special digraph to be disguised into the software's control-flow graph, was later patented [24]. Other original ideas, improvements and surveys on the available methods have been contributed by many authors ever since. See, for example, [10, 11, 12, 15, 21, 26, 27].

Willing to prevent the timely retrieval of the encoded identification data, malicious agents may attempt to tamper with the watermark. A watermark solution is therefore only as secure as it is able to resist attacks of various sorts. Naturally, a lot of research has been put up lately towards developing more resilient solutions as well as strengthening existing ones. This paper pursues this latter goal.

We consider the graph-based watermarking scheme introduced by Collberg, Kobourov, Carter and Thomborson [10], and afterwards developed and improved upon by Chroni and Nikolopoulos in a series of papers [4, 5, 6, 7, 8]. These latter authors proposed a watermark graph belonging to a subclass of the reducible permutation graphs introduced by the former authors. Though the mechanics of encoding and decoding the proposed watermark is well described in [6], such special subclass of reducible permutation graphs has not been fully characterized. We provide such a characterization, based solely on the topology of the graph, along with a linear-time recognition algorithm. From an application standpoint, the recognition algorithm allows for the polynomial-time recovery of watermarks that have undergone the malicious removal of a some edges, whenever that is at all possible (otherwise the algorithm outputs a list of all watermarks that could have originated the tampered-with watermark at hand). On a minor note, we formulate a simpler linear-time decoding algorithm for Chroni and Nikolopoulos's watermarks.

This paper is organized as follows. In Section 2, we present some preliminary concepts related to graph-based software watermarking, including the most common forms of attacks. In Section 3, we recall the watermark from Chroni and Nikolopoulos, and we state a number of structural properties, the proofs of which we delay until Section 7 for the sake of readability. In

Section 4, we define and characterize the family of canonical reducible permutation graphs, which correspond to the watermarks produced by Chroni and Nikolopoulos’s encoding function.

In Section 5, we propose a robust polynomial-time algorithm that, given a watermark with *whatever* constant number  $k$  of missing edges, either recovers the encoded data or proves that the watermark has become irretrievably damaged. In Section 6, we formulate a simpler linear-time decoding algorithm.

Finally, Section 7 contains the postponed proofs for the properties stated in Section 3, and Section 8 concludes the paper with our final remarks.

Throughout the text, we let  $V(G)$  and  $E(G)$  respectively denote, as usual, the vertex set and edge set of a given graph  $G$ . Also, we let  $N_G^+(v)$  and  $N_G^-(v)$  be the sets of out-neighbors and in-neighbors of vertex  $v$  in  $G$ , with  $d_G^+(v)$  and  $d_G^-(v)$  their respective sizes. If  $J$  is a subset of either  $V(G)$  or  $E(G)$ , then  $G - J$  corresponds to the graph obtained from  $G$  by the removal of  $J$ .

## 2 Graph-based software watermarking

Software watermarking schemes provide the necessary means of embedding identification data—typically a copyright notice or a customer number—into a piece of software. We refer to the identification data as the *identifier*, and we may regard it as an integer, for simplicity. In short, software watermarks are appropriate embeddings of surreptitious identifiers into computer programs, and they can be broadly divided into two categories: static and dynamic [9]. The former are embedded in the code, whereas the latter are embedded into the program’s execution state at runtime.

A static, *graph-based* watermarking scheme usually consists of four algorithms:

- an *encoder*, which converts the identifier into a graph—the watermark;
- an *embedder*, a function whose input parameters are the software itself (either the binary code or the source code in some programming language), the intended watermark, and possibly some secret key, and whose output is a modified software containing the watermark;
- an *extractor*, which retrieves the watermark graph from the watermarked software; and
- a *decoder*, which extracts the identifier from the watermark;

To every computer program one can associate a directed graph representing the possible sequences of instructions, where each vertex corresponds to a maximal block of contiguous instructions. Such graph, called the *control-flow graph* (CFG) of the software [1], can be obtained by means of static

analysis [18, 25]. What the embedder does is basically to insert dummy code into the program so that the intended watermark graph shows up as an induced subgraph of the CFG. The position of the watermark graph within the CFG is often determined as a function of a secret key. Knowledgeable of the secret key, the extractor retrieves that subgraph, which is then passed along to the decoding algorithm. Among the existing tools for embedding/extracting graph-based watermarks, we cite Collberg’s SandMark project [13]. In this paper, we focus on the encoding/decoding algorithms described by Chroni and Nikolopoulos in [6].

**Attacks** Among the several different kinds of attacks against graph-based watermarks, we list the following:

- *additive* attacks, in which other watermarks are inserted into the same object, generating ambiguity;
- *subtractive* attacks, in which the watermark is removed altogether; and
- *distortive* attacks, in which the watermark graph is modified to confound the decoder.

Additive and subtractive attacks can be precluded to a great extent by techniques of cryptography and software diversity [20]. On the other hand, distortive attacks—also known as *jamming* attacks—are more difficult to deal with. In some cases, the distortive attacker may even be able to reverse engineer the entire code and apply semantics-preserving modifications which modify the CFG structurally without affecting the software’s functionalities. Distortive attacks are arguably the most important attack model one should worry about [23].

The algorithm described in Section 5 targets watermarks that were subject to distortive attacks in the form of *edge removals*. The removal of an edge can be attained by simply replacing a jump instruction with a NOP code (a void instruction). Although it is conceivable that the attacker *inserts* edges into the graph, in practice the addition of jumps to arbitrary locations in the program’s binaries (making new edges appear on the CFG) is very likely to cause a program crash. The same goes for the insertion or removal of *vertices*, where the attacker would have to fix all the instructions’ offsets in order to keep the functionalities of the program intact, which would be all but trivial.

### 3 The watermark from Chroni and Nikolopoulos

We recall the encoding algorithm described in [6]. The index of the first element in all considered sequences is 1.

Let  $\omega$  be a positive integer identifier, and  $n$  the size of the binary representation  $B$  of  $\omega$ . Let also  $n_0$  and  $n_1$  be the number of 0's and 1's, respectively, in  $B$ , and let  $f_0$  be the index of the leftmost 0 in  $B$ . The extended binary  $B^*$  is obtained by concatenating  $n$  digits 1, followed by the one's complement of  $B$  and by a single digit 0. We let  $n^* = 2n + 1$  denote the size of  $B^*$ , and we define  $Z_0 = (z_i^0), i = 1, \dots, n_1 + 1$ , as the ascending sequence of indexes of 0's in  $B^*$ , and  $Z_1 = (z_i^1), i = 1, \dots, n + n_0$ , as the ascending sequence of indexes of 1's in  $B^*$ .

Let  $S$  be a sequence of integers. We denote by  $S^R$  the sequence formed by the elements of  $S$  in backward order. If  $S = (s_i)$ , for  $i = 1, \dots, t$ , and there is an integer  $k \leq t$  such that the subsequence consisting of the elements of  $S$  with indexes less than or equal to  $k$  is ascending, and the subsequence consisting of the elements of  $S$  with indexes greater than or equal to  $k$  is descending, then we say  $S$  is *bitonic*. If all  $t$  elements of a sequence  $S$  are distinct and belong to  $\{1, \dots, t\}$ , then  $S$  is a *permutation*. If  $S$  is a permutation of size  $t$ , and, for all  $1 \leq i \leq t$ , the equality  $i = s_{s_i}$  holds, then we say  $S$  is *self-inverting*. In this case, the unordered pair  $(i, s_i)$  is called a *2-cycle* of  $S$ , if  $i \neq s_i$ , and a *1-cycle* of  $S$ , if  $i = s_i$ . If  $S_1, S_2$  are sequences (respectively, paths in a graph), we denote by  $S_1 || S_2$  the sequence (respectively, path) formed by the elements of  $S_1$  followed by the elements of  $S_2$ .

Back to Chroni and Nikolopoulos's algorithm, we define  $P_b = (b_i)$ , with  $i = 1, \dots, n^*$ , as the bitonic permutation  $Z_0 || Z_1^R$ . Finally, the self-inverting permutation  $P_s = (s_i)$  is obtained from  $P_b$  as follows: for  $i = 1, \dots, n^*$ , element  $s_{b_i}$  is assigned value  $b_{n^*-i+1}$ , and element  $s_{b_{n^*-i+1}}$  is assigned value  $b_i$ . In other words, the 2-cycles of  $P_s$  correspond to the  $n$  unordered pairs of distinct elements of  $P_b$  that share the same minimum distance to one of the extremes of  $P_b$ , that is, the pairs  $(p, q) = (b_i, b_{n^*-i+1})$ , for  $i = 1, \dots, n$ . Since the central index  $i = n + 1$  of  $P_b$  is the solution of equation  $n^* - i + 1 = i$ , element  $b_{n+1}$  — and no other — will constitute a 1-cycle in  $P_s$ . We refer to such element of  $P_s$  as its *fixed element*, and we let  $f$  denote it.

The watermark generated by Chroni and Nikolopoulos's encoding algorithm [6] is a directed graph  $G$  whose vertex set is  $\{0, 1, \dots, 2n + 2\}$ , and whose edge set contains  $4n + 3$  edges, to wit: a *path edge*  $(u, u - 1)$  for  $u = 1, \dots, 2n + 2$ , constituting a Hamiltonian path that will be unique in  $G$ , and a *tree edge* from  $u$  to  $q(u)$ , for  $u = 1, \dots, n^*$ , where  $q(u)$  is defined as the vertex  $v > u$  with the greatest index in  $P_s$  to the left of  $u$ , if such  $v$  exists, or  $2n + 2$  otherwise. The rationale behind the name *tree edge* is the fact that such edges induce a spanning tree of  $G \setminus \{0\}$ .

Let us glance at an example. For  $\omega = 43$ , we have  $B = 101011$ ,  $n = 6$ ,  $n_0 = 2$ ,  $n_1 = 4$ ,  $f_0 = 2$ ,  $B^* = 111110101000$ ,  $n^* = 13$ ,  $Z_0 = (7, 9, 11, 12, 13)$ ,  $Z_1 = (1, 2, 3, 4, 5, 6, 8, 10)$ ,  $P_b = (7, 9, 11, 12, 13, 10, 8, 6, 5, 4, 3, 2, 1)$ ,  $P_s = (7, 9, 11, 12, 13, 10, 1, 8, 2, 6, 3, 4, 5)$  and  $f = 8$ . The watermark graph associated to  $\omega$  presents, along with the path edges in the Hamiltonian path  $14, 13, \dots, 0$ ,

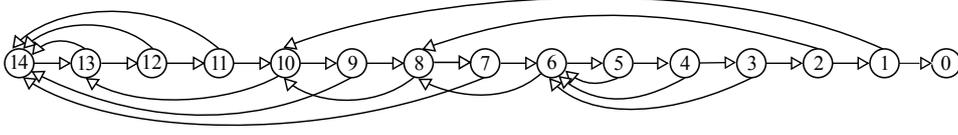

Figure 1: Watermark for identifier  $\omega = 43$ .

the tree edges  $(1, 10), (2, 8), (3, 6), (4, 6), (5, 6), (6, 8), (7, 14), (8, 10), (9, 14), (10, 13), (11, 14), (12, 14)$  and  $(13, 14)$ , as illustrated in Figure 1.

### 3.1 Structural properties

We now state a number of properties concerning the watermark from Chroni and Nikolopoulos and the special permutations they are associated to. These properties, whose proofs are given in Section 7, set the basis for the characterization of the class of canonical reducible permutation graphs, which is given in Section 4.

For all properties stated below, let  $G$  be the watermark graph associated to an identifier  $\omega$  of size  $n$ , and let  $P_b$  and  $P_s$  be, respectively, the bitonic and the self-inverting permutations dealt with during the construction of  $G$ .

**Property 1.** *For  $1 \leq i \leq n$ , the element  $b_{n+i+1}$  in  $P_b$  is equal to  $n - i + 1$ , that is, the  $n$  rightmost elements in  $P_b$ , from right to left, are  $1, \dots, n$ .*

**Property 2.** *The elements with indexes  $1, \dots, n$  in  $P_s$  are all greater than  $n$ .*

**Property 3.** *The fixed element  $f$  satisfies  $f = n + f_0$ , unless the identifier  $\omega$  is equal to  $2^k - 1$  for some integer  $k$ , whereupon  $f = n^* = 2n + 1$ .*

**Property 4.** *In self-inverting permutation  $P_s$ , elements indexed  $1, \dots, f - n - 1$  are respectively equal to  $n + 1, n + 2, \dots, f - 1$ , and elements indexed  $n + 1, n + 2, \dots, f - 1$  are respectively equal to  $1, \dots, f - n - 1$ .*

**Property 5.** *The first element in  $P_s$  is  $s_1 = n + 1$ , and the central element in  $P_s$  is  $s_{n+1} = 1$ .*

**Property 6.** *If  $f \neq n^*$ , then the index of element  $n^*$  in  $P_s$  is equal to  $n_1 + 1$ , and vice-versa. If  $f = n^*$ , then the index of element  $n^*$  in  $P_s$  is also  $n^*$ .*

**Property 7.** *The subsequence of  $P_s$  consisting of elements indexed  $1, \dots, n + 1$  is bitonic.*

**Property 8.** *For  $u \leq 2n$ ,  $(u, 2n + 2)$  is a tree edge of watermark  $G$  if, and only if,  $u - n$  is the index of a digit 1 in the binary representation  $B$  of the identifier  $\omega$  represented by  $G$ .*

**Property 9.** *If  $(u, k)$  is a tree edge of watermark  $G$ , with  $k \neq 2n + 2$ , then*

- (i) *element  $k$  precedes  $u$  in  $P_s$ ; and*
- (ii) *if  $v$  is located somewhere between  $k$  and  $u$  in  $P_s$ , then  $v < u$ .*

## 4 Canonical reducible permutation graphs

This section is devoted to the characterization of the class of canonical reducible permutation graphs. After describing some terminology and proving some preliminary results, we define the class using purely graph-theoretical predicates. Then, we show it corresponds exactly to the set of watermarks produced by Chroni and Nikolopoulos's encoding algorithm [6]. Finally, we characterize it in a way that allows for efficient algorithms to recover from distortive attacks.

A *reducible flow graph* [16, 17, 22] is a directed graph  $G$  with a source  $s \in V(G)$ , such that, for each cycle  $C$  of  $G$ , every directed path from  $s$  to  $C$  reaches  $C$  at the same vertex. It is well known that a reducible flow graph has at most one Hamiltonian cycle [10].

**Definition 10.** A self-labeling reducible flow graph is a directed graph  $G$  such that

- (i)  $G$  presents exactly one directed Hamiltonian path  $H$ , hence there is a unique labeling function  $\sigma : V(G) \rightarrow \{0, 1, \dots, |V(G)| - 1\}$  of the vertices of  $G$  such that the order of the labels along  $H$  is precisely  $|V(G)| - 1, |V(G)| - 2, \dots, 0$ ; and,
- (ii) considering the labeling  $\sigma$  as described,  $N_G^+(0) = \emptyset$ ,  $N_G^-(0) = \{1\}$ ,  $N_G^+(|V(G)| - 1) = \{|V(G)| - 2\}$ ,  $|N_G^- (|V(G)| - 1)| \geq 2$ , and, for all  $v \in V(G) \setminus \{0, |V(G)| - 1\}$ ,  $N_G^+(v) = \{v - 1, w\}$ , for some  $w > v$ .

From now on, without loss of generality, we shall take  $\sigma$  for granted and assume the vertex set of any self-labeling reducible flow graph  $G$  is the very set  $V(G) = \{0, 1, \dots, |V(G)| - 1\}$ . By doing so, we may simply compare two vertices, e.g.  $v > u$  (or  $v$  greater than  $u$ , in full writing), whereas we would otherwise need to compare their images under  $\sigma$ , e.g.  $\sigma(v) > \sigma(u)$ .

**Definition 11.** The representative tree  $T$  of a self-labeling reducible flow graph  $G$  with Hamiltonian path  $H$  has vertex set  $V(T) = V(G) \setminus \{0\}$  and edge set  $E(T) = E(G) \setminus E(H)$ , where all edges are deprived of their orientation.

First of all, note that  $T$  is indeed acyclic (the ascending order of its vertices' labels constitutes a trivial topological sort) and connected (there is only one sink, namely vertex  $|V(G)| - 1$ ). A representative tree  $T$  is always regarded as a *rooted* tree whose root is  $|V(G)| - 1$ . Moreover, it is regarded as an *ordered* tree, that is, for each  $v \in V(T)$ , the children of  $v$  are always considered according to an ascending order of their labels. For  $v \in T$ , we denote by  $N_T^*(v)$  the set of descendants of  $v$  in  $T$ . Figure 2 depicts two representative trees.

**Observation 12.** The representative tree  $T$  of a self-labeling reducible flow graph  $G$  satisfies the *max-heap property*, that is, if vertex  $u$  is a child of vertex  $v$  in  $T$ , then  $v > u$ .

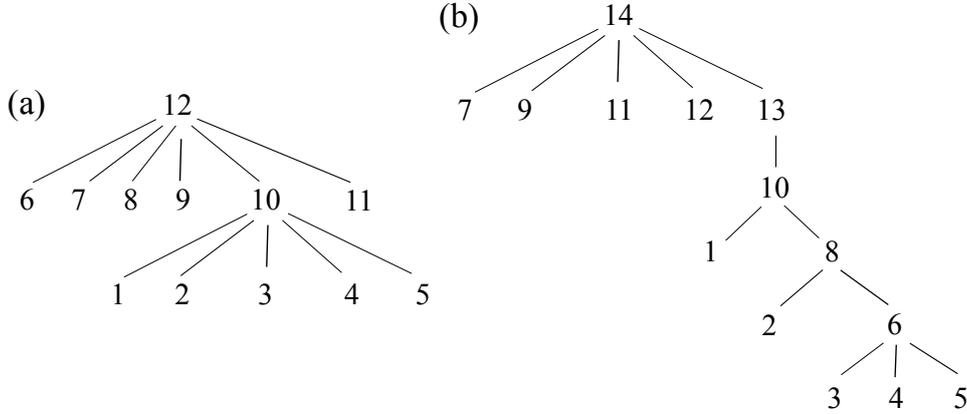

Figure 2: Representative trees of the watermark graphs produced by Chroni and Nikolopoulos’s encoding algorithm for identifiers (a)  $\omega = 31$  and (b)  $\omega = 43$  (the full watermark for  $\omega = 43$  is shown in Figure 1). It is easy to check that such graphs are self-labeling reducible flow graphs.

*Proof:* Direct from the way  $T$  is rooted and from property (ii) in the definition of self-labeling reducible flow graphs, whereby the in-neighbors of  $w$  in  $G \setminus E(H)$  comprise only vertices  $v < w$ . We convey the idea that a representative tree  $T$  satisfies the max-heap property by saying that  $T$  is a *descending*, ordered, rooted tree.  $\square$

**Definition 13.** Let  $S = (s_i), i = 1, \dots, 2n + 1$ , be a self-inverting permutation. We say  $S$  is canonical if:

- (i) there is exactly one 1-cycle in  $S$ ;
- (ii) each 2-cycle  $(s_i, s_j)$  of  $S$  satisfies  $1 \leq i \leq n$ , for  $s_i > s_j$ ;
- (iii)  $s_1, \dots, s_{n+1}$  is a bitonic subsequence of  $S$  starting at  $s_1 = n + 1$  and ending at  $s_{n+1} = 1$ .

**Lemma 14.** In any canonical self-inverting permutation, the fixed element  $f$  satisfies  $f \in [n + 2, 2n + 1]$ .

*Proof:* By property (ii) of canonical self-inverting permutations, each 2-cycle of  $S$  must contain at least one element whose index  $i$  satisfies  $1 \leq i \leq n$ . From property (i), and given the size of  $S$ , it follows that the number of 2-cycles in  $S$  is  $n$ , hence, by the pigeonhole principle, each and every 2-cycle in  $S$  contains *exactly* one such element  $s_i$  with  $1 \leq i \leq n$ . But this means the other element in each 2-cycle, namely  $s_j$ , satisfies  $s_j \in [n + 1, 2n + 1]$ . Since there are  $n + 1$  values in that range and only  $n$  such elements  $s_j$ , there must be exactly one element  $s_k \in [n + 1, 2n + 1]$  which is not part of a 2-cycle,

and therefore  $s_k = f$ . Now, by property (iii),  $n + 1 = s_1$ , hence  $f \neq n + 1$ , and the lemma follows.  $\square$

Let  $T$  be a representative tree. The *preorder traversal*  $P$  of  $T$  is a sequence of its vertices that is recursively defined as follows. If  $T$  is empty,  $P$  is also empty. Otherwise,  $P$  starts at the root  $r$  of  $T$ , followed by the preorder traversal of the subtree whose root is the smallest child of  $r$ , followed by the preorder traversal of the subtree whose root is the second smallest child of  $r$ , and so on. The last (rightmost) element of  $P$  is also referred to as the rightmost element of  $T$ .

**Lemma 15.** *The preorder traversal of a representative tree  $T$  is unique. Conversely, a representative tree  $T$  is uniquely determined by its preorder traversal.*

*Proof:* We use induction on  $|V(T)|$ . If  $|V(T)| \leq 1$ , the lemma holds trivially. Let  $|V(T)| > 1$ , and let  $v_k$  be the uniquely defined leaf of  $T$  for which the path  $v_1, \dots, v_k$  from the root  $v_1$  of  $T$  to  $v_k$  has the property that each  $v_i$ , for  $1 < i \leq k$ , is the greatest vertex among the children of  $v_{i-1}$ . By the induction hypothesis, the preorder traversal  $P'$  of  $T \setminus \{v_k\}$  is unique. Because  $v_k$  is necessarily the rightmost vertex of  $T$ , the preorder traversal  $P$  of  $T$  is uniquely determined as  $P' || v_k$ .

Conversely, let  $P$  be a preorder traversal of some representative tree  $T$ . If  $|P| \leq 1$ , there is nothing to prove. Otherwise, suppose the lemma holds for preorder traversals of size  $\leq k$ , and consider  $|P| = k$ . Let  $v_k$  be the rightmost element of  $P$ . Clearly,  $v_k$  must be a leaf of  $T$ , and also the rightmost (i.e., greatest) vertex among the children of its parent. Now define  $P' = P - \{v_k\}$ . By the induction hypothesis, there is a unique tree  $T'$  whose preorder traversal is  $P'$ . Let  $v_{k-1}$  be the rightmost element of  $P'$ . We obtain  $T$  from  $T'$ , by making  $v_k$  the rightmost child of the smallest ancestor  $v_j$  of  $v_{k-1}$  satisfying  $v_j > v_k$ , so  $P$  is clearly the preorder traversal of  $T$ . Since no other parent for  $v_k$  would be possible without breaking the ascending order of siblings in a representative tree,  $T$  is uniquely defined by  $P$ .  $\square$

The first element of the preorder traversal  $P$  of a tree  $T$  is always its root. If we remove the first element of  $P$ , the remaining sequence is said to be the *root-free* preorder traversal of  $T$ .

We can now define the class of canonical reducible permutation graphs.

**Definition 16.** *A canonical reducible permutation graph  $G$  is a self-labeling reducible flow graph on  $2n + 3$  vertices, for some integer  $n \geq 1$ , such that the root-free preorder traversal of the representative tree of  $G$  is a canonical self-inverting permutation.*

**Lemma 17.** *If  $G$  is a watermark instance produced by Chroni and Nikolopoulos's encoding algorithm [6], then  $G$  is a canonical reducible permutation graph.*

*Proof:* Recall, from Section 3, that the watermark graph  $G$  associated to identifier  $\omega$ , whose binary representation  $B$  has size  $n$ , is constructed with vertex set  $V(G) = \{0, \dots, 2n + 2\}$  and an edge set  $E(G)$  which can be partitioned into path edges and tree edges in such a way that all conditions in the definition of self-labeling reducible flow graphs are satisfied, as can be easily checked. Now, by Property 9 of Chroni and Nikolopoulos's watermarks (see Section 3.1), the tree edges of  $G$  constitute a representative tree  $T$  of  $G$  whose root-free preorder traversal is precisely the self-inverting permutation  $P_s$  determined by the encoding algorithm from [6] as a function of  $B$ . Consequently, what is left to prove is that  $P_s$  is canonical. The first condition to  $P_s$  being canonical is asserted by Property 3 in Section 3.1 (the fixed element  $f$  corresponds to the unique 1-cycle in  $P_s$ ); the second condition is given by Property 2; and, finally, Properties 5 and 7 fulfill the third condition, therefore  $P_s$  is canonical.  $\square$

**Lemma 18.** *If  $G$  is a canonical reducible permutation graph, then  $G$  is the watermark produced by Chroni and Nikolopoulos's encoding algorithm [6] for some integer identifier  $\omega$ .*

*Proof:* Let  $G$  be a canonical reducible permutation graph, and  $T$  its representative tree. By Lemma 15,  $T$  is uniquely defined by its preorder traversal  $P$ . We show that  $P$  corresponds to the self-inverting permutation  $P_s$  generated by the encoding algorithm of [6] (please refer to Section 3 for details) when computing the watermark for some integer identifier  $\omega$ . By definition,  $P = (s_i), i = 1, \dots, 2n + 1$ , is a canonical self-inverting permutation presenting a single 1-cycle  $f$  and a number  $n$  of 2-cycles  $(p, q)$ . Those 2-cycles  $(p, q)$  define exactly one bitonic permutation  $P_b = (b_j), j = 1, \dots, 2n + 1$  satisfying Property 1 of Chroni and Nikolopoulos's watermarks with

- (i)  $b_{n+1} = f$ , and,
- (ii) for all  $j \in \{1, \dots, n\}$ ,  $b_j = p$  if and only if  $b_{2n+1-j} = q$ .

Such bitonic permutation  $P_b$  can be regarded as  $Z_0 || Z_1^R$  by assigning to  $Z_0$  the prefix of  $P_b$  comprising its maximal ascending subsequence, and now the indexes of 0's and 1's in the extended binary  $B^*$  are totally determined. We proceed by extracting the binary  $B$  that is the one's complement of the subsequence of  $B^*$  with digits from the  $(n + 1)$ th to the  $(2n)$ th position in  $B^*$ . Regarding  $B$  as the binary representation of a positive integer  $\omega$ , the image of such  $\omega$  under the encoding function of Chroni and Nikolopoulos is isomorphic to  $G$ .  $\square$

We proceed to the last definitions before we can give an appropriate, algorithmic-flavored characterization of canonical reducible permutation

graphs. Let  $T$  be the representative tree of some canonical reducible permutation graph  $G$ , and  $P$  a canonical self-inverting permutation corresponding to the root-free preorder traversal of  $T$ . We refer to the fixed element  $f$  of  $P$  also as the fixed element (or vertex) of both  $G$  and  $T$ . Similarly, the 2-cyclic elements of  $P$  correspond to *cyclic* elements (or vertices) of both  $G$  and  $T$ . A vertex  $v \in V(T) \setminus \{2n+2\}$  is considered *large* when  $n < v \leq 2n+1$ ; otherwise,  $v \leq n$  and  $v$  is dubbed as *small*. Denote by  $X, Y$ , respectively, the subsets of large and small vertices in  $T$ , so  $|X| = n+1$  and  $|Y| = n$ . By Lemma 14,  $f \in X$ . We then define  $X_c = X \setminus \{f\} = \{x_1, \dots, x_n\}$  as the set of large cyclic vertices in  $T$ .

**Definition 19.** A representative tree  $T$  is a Type-1 tree — see Figure 3(a) — if

- (i)  $n+1, n+2, \dots, 2n+1$  are children of the root  $2n+2$  in  $T$ ; and
- (ii)  $1, 2, \dots, n$  are children of  $2n$ .

**Definition 20.** A representative tree  $T$  is a Type-2 tree relative to  $f$  — see Figure 3(b) — if

- (i)  $n+1 = x_1 < x_2 < \dots < x_\ell = 2n+1$  are the children of  $2n+2$ , for some  $\ell \in [2, n-1]$ ;
- (ii)  $x_i > x_{i+1}$  and  $x_i$  is the parent of  $x_{i+1}$ , for all  $i \in [\ell, n-1]$ ;
- (iii)  $1, 2, \dots, f-n-1$  are children of  $x_n$ ;
- (iv)  $x_i = n+i$ , for  $1 \leq i \leq f-n-1$ ;
- (v)  $f$  is a child of  $x_q$ , for some  $q \in [\ell, n]$  satisfying  $x_{q+1} < f$  whenever  $q < n$ ; and
- (vi)  $N_T^*(f) = \{f-n, f-n+1, \dots, n\}$  and  $y_i \in N_T^*(f)$  has index  $x_{y_i} - f + 1$  in the preorder traversal of  $N_T^*[f]$ .

**Lemma 21.** If  $y_r$  is the rightmost vertex of a Type-2 representative tree  $T$  relative to some  $f \neq 2n+1$ , then  $y_r$  is equal to the number  $\ell$  of children of the root  $2n+2$  in  $T$ .

*Proof:* By the definition of a Type-2 representative tree, the only non-leaf child of the root  $2n+2$  of  $T$  is its rightmost child  $x_\ell$ , therefore each child  $x_i$  of  $2n+2$ , for  $1 \leq i \leq \ell$ , appears precisely at the  $i$ th position in the root-free preorder traversal  $P$  of  $T$ . Since, by definition,  $P$  is self-inverting, and  $y_r$  is the last,  $(2n+1)$ th element of  $P$ , it follows that  $y_r$  must be equal to the index of  $2n+1 = x_\ell$  in  $P$ , that is,  $y_r = \ell$ .  $\square$

The following theorem characterizes canonical reducible permutation graphs in terms of the above defined trees.

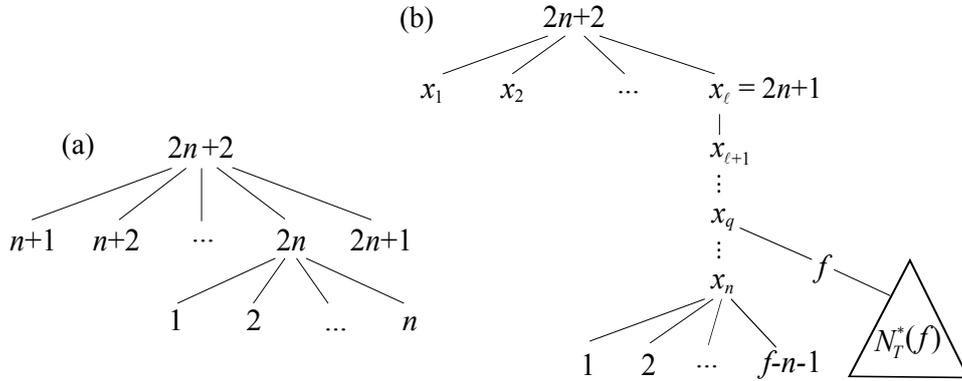

Figure 3: (a) A Type-1 representative tree. (b) A Type-2 representative tree.

**Theorem 22.** *A digraph  $G$  is a canonical reducible permutation graph if, and only if,  $G$  is a self-labeling reducible flow graph and*

- (i) *the fixed element of  $G$  is  $2n + 1$  and  $G$  has a Type-1 representative tree; or*
- (ii) *the fixed element of  $G$  belongs to  $[n + 2, 2n]$  and  $G$  has a Type-2 representative tree.*

*Proof:* Let  $G$  be a canonical reducible permutation graph and  $T$  its representative tree. By definition,  $G$  is a self-labeling reducible flow graph. Let  $P = s_1, \dots, s_{2n+1}$  be the root-free preorder traversal of  $T$ , hence a canonical self-inverting permutation, also by definition. This means, among other things, that  $P$  has a unique fixed element  $f$ , and that  $P' = s_1, \dots, s_{n+1}$  is a bitonic subsequence of  $P$ . Since  $T$  is descending, it follows that the prefix  $A$  of  $P'$  constituting its maximal ascending subsequence must comprise solely vertices that are children of the root  $2n+2$ , the rightmost of which certainly being  $2n+1$ .

First, let  $f = 2n+1$ . Since  $f$  constitutes a 1-cycle of  $P$ ,  $f$  must occupy the rightmost,  $(2n+1)$ th position in  $P$ , hence  $f$  is a leaf of  $T$ . Furthermore, by Property 4 of canonical reducible permutation graphs, it follows that  $P'$  consists of elements  $n+1, n+2, \dots, 2n, 1$ , hence  $A = n+1, n+2, \dots, 2n$ , and these vertices are therefore children of  $2n+2$  in  $T$ . Now, again by Property 4, elements  $1, \dots, n$  appear, in this order, to the right of  $A$  in  $P$ . Considering that  $P$  is a preorder traversal and a representative tree satisfies the max-heap property, we conclude that vertices  $1, \dots, n$  can only be children of  $2n$ , hence  $T$  is a Type-1 tree, as required.

Next, suppose  $f < 2n+1$ . By Lemma 14, it follows that  $f \in [n+2, 2n]$ . We already know that the children of  $2n+2$  are the vertices of  $A$ . Let  $D$  be the subset formed by the remaining vertices of  $P'$ . Clearly, the vertices of  $D$

must appear in descending order. Since  $T$  satisfies the max-heap property and  $P$  is a preorder traversal of  $T$ , it follows that the largest vertex of  $D$  is a child of  $2n + 1$ , and subsequently each vertex in  $D$  is the parent in  $T$  of the vertex placed to its left along the sequence  $D$ . Again, because  $T$  satisfies the max-heap property,  $f \in [2n + 2, 2n]$  must be the child of the smallest vertex  $x_q \in D \cup \{2n + 1\}$  satisfying  $x_q > f$ . Let us again examine the ascending subsequence  $A$ . We know that the first vertex of  $A$  is  $n + 1$ . Suppose the leading  $k$  vertices of  $A$  are  $n + 1, n + 2, \dots, n_k$ , for some  $k$ . Because  $P$  is self-inverting, it follows that the vertices  $1, 2, \dots, k$  must be the children of the last (i.e., smallest) vertex of  $D$ , and  $k = f - n - 1$  by Property 4. It remains solely to describe how the remaining small vertices, namely  $f - n, f - n + 1, \dots, n$ , are placed in  $T$ . Since they appear after  $f$  in  $P$ , it can only be that this subset comprises exactly the descendants  $N_T^*(f)$  of  $f$  in  $T$ . Each of the vertices  $y \in N_T^*(f)$  constitute a 2-cycle with some vertex  $x$  belonging to the bitonic subsequence  $P'$ , hence the index of  $y$  in  $P$  is exactly  $x$ , and all the conditions for a Type-2 tree have thus been verified.

Conversely, let  $G$  be a self-labeling reducible flow graph. First, suppose that (i) applies and let  $T$  be the corresponding Type-1 representative tree. Then the root-free preorder traversal  $P$  of  $T$  is

$$n + 1, n + 2, \dots, 2n, 1, 2, \dots, n, 2n + 1.$$

Regarding  $P$  as a permutation of  $\{1, \dots, 2n+1\}$ , we observe that  $2n + 1$  is the only fixed vertex on it; for  $1 \leq i \leq n$ , each element  $n+i$  of  $P$  has index  $i$ , while  $i$  has index  $n+i$ , and  $n+1, n+2, \dots, 2n, 1$  form a bitonic subsequence of  $P$ . Consequently,  $P$  is a canonical self-inverting permutation, and  $G$  is a canonical reducible permutation graph.

Finally, suppose (ii) applies. Let  $T$  be the corresponding Type-2 representative tree relative to some  $f \in [n + 2, 2n]$ . The root-free preorder traversal  $P$  of  $T$  consists of

$$x_1, \dots, x_\ell, x_{\ell+1}, \dots, x_q, x_{q+1}, \dots, x_n, 1, 2, \dots, f - n - 1, f, P(N_T^*(f)),$$

where  $x_1 = n+1$ ;  $x_\ell = 2n+1$ ;  $x_i = n+i$  for  $1 \leq i \leq f-n-1$ ;  $x_1, x_2, \dots, x_n, 1$  is a bitonic subsequence of  $P$ ; and  $P(N_T^*(f))$  denotes the preorder traversal of the vertices of  $N_T^*(f)$ , in which each  $y_i \in N_T^*(f)$  has index  $x_{y_i} - f + 1$ . Observe that, for  $1 \leq i \leq f - n - 1$ ,  $(n + i, i)$  constitutes a 2-cycle in  $P$ . Moreover, for  $f - n \leq i \leq n$ , vertex  $x_i$  forms a 2-cycle with an element  $y_j \in N_T^*(f)$ . All conditions have been met, thus  $P$  is a canonical self-inverting permutation and  $G$  is a canonical reducible permutation graph.  $\square$

**Corollary 23.** *Recognizing whether a graph  $G(V, E)$  is a canonical reducible permutation graph can be achieved in  $O(|V|)$  time.*

*Proof:* Direct from Theorem 22 and from the definitions of self-labeling reducible flow graphs, Type-1 and Type-2 representative trees, all of whose conditions can be verified in linear time easily.  $\square$

## 5 Coping with missing edges

The linear-time recognition of the class of canonical reducible permutation graphs, wrapped up in the form of Corollary 4, allows for the construction of a polynomial-time algorithm to recover watermarks which have been deprived of  $k$  edges, for any fixed integer  $k$ . The proposed algorithm is formally robust [19], since it manages to repair a damaged watermark  $G'$  whenever such a thing is possible; otherwise, rather than producing an incorrect result, it shows that  $G'$  does not belong to the family of damaged watermarks that can possibly be recovered. As a certificate for this latter case, it outputs the set of watermarks that may become isomorphic to  $G'$  through the removal of exactly  $k$  of their edges, thus proving that the intended restore is not at all possible.

Let  $G$  be a watermark and  $G'$  the graph obtained from  $G$  when a certain subset of  $k$  edges are removed. The idea is simple. The algorithm attempts the addition to  $E(G')$  of each and every  $k$ -subset of non-edges of  $G'$ , one subset at a time. After each attempt, it checks whether a valid watermark (i.e., a canonical reducible permutation graph) was produced. If, after trying all subsets, only one graph was recognized as such, then the decoding was successful. Otherwise, it displays a set containing all watermark candidates.

Since  $|V(G')| = 2n + 3$  and  $|E(G')| = 4n + 3 - k$ , the number of  $k$ -subsets of non-edges of  $G'$  is

$$\binom{\binom{2n+3}{2} - (4n + 3 - k)}{k} = \mathcal{O}(n^{2k}).$$

Thus, considering the effort of running the recognition algorithm for each one of these watermark candidates, the algorithm runs in overall  $\mathcal{O}(n^{2k}) \cdot \mathcal{O}(n) = \mathcal{O}(n^{2k+1})$  time.

The aforementioned formulation considers that every non-edge of  $G'$  could be an edge of the original watermark. However, owing to the particular structure of canonical reducible permutation graphs, relatively few among those non-edges do really stand a chance of belonging to  $G$ . More precisely, every vertex  $v$  of  $G$  has out-degree at most 2, hence  $v$  must be the tail endpoint of a most  $2 - |N_{G'}^+(v)|$  edges. The multiset  $M^*$  of all candidates

to being the tail of a missing edge has therefore

$$\begin{aligned}
|M^*| &= \sum_{v \in V(G')} (2 - |N_{G'}^+(v)|) \\
&= 2 \cdot |V(G')| - \sum_{v \in V(G')} |N_{G'}^+(v)| \\
&= 2 \cdot |V(G')| - |E(G')| \\
&= 2 \cdot (2n + 3) - (4n + 3 - k) = k + 3
\end{aligned}$$

elements (not necessarily distinct), and therefore the  $k$  missing edge tails may be chosen in  $\binom{|M^*|}{k} = \mathcal{O}(k^3)$  different ways. For each  $k$ -subset of  $M^*$ , the algorithm must choose the head corresponding to each tail, which can be done in  $\mathcal{O}(n)$  ways per edge, for an overall  $\mathcal{O}(k^3 n^k)$  number of  $k$ -subsets of non-edges that shall be tentatively added to  $G'$ . With the  $\mathcal{O}(n)$  running time of the recognition algorithm for each such attempt, the complexity of the whole decoding algorithm is an overall  $\mathcal{O}(k^3 n^{k+1})$ .

As a matter of fact, it is still possible to eliminate a whole  $\mathcal{O}(k^3)$  factor from that asymptotical complexity, if the labels of the vertices are known. To assume that the labels are known is reasonable in many situations, since each vertex corresponds to a block in the CFG of the software, and, by construction, the watermark graph possesses a Hamiltonian path  $2n+2, 2n+1, \dots, 0$  that corresponds, in the CFG, to a chunk of subsequent blocks. If that is the case, then we know the out-degree, in  $G$ , of all watermark vertices (the tail and the head of the Hamiltonian path have out-degrees 1 and 0, respectively; all other vertices have out-degree 2) and, consequently, the tails of all missing edges. By running the linear-time recognition algorithm on each possible choice of heads, the decoding algorithm has an overall  $\mathcal{O}(n^{k+1})$  time complexity.

## 6 A simpler decoding algorithm

We conclude with a new decoding algorithm for Chroni and Nikolopoulos's watermarks. Even though the running time of their seminal decoding algorithm is also linear [6], our formulation (see Algorithm 1) is notably simpler. Building on the proofs of some of the properties considered in Section 3.1, the analysis that follows turns out to be rather easy.

**Theorem 24.** *Algorithm 1 correctly retrieves the identifier encoded by a canonical reducible permutation graph  $G$  in linear time.*

*Proof:* Let  $G$  be a canonical reducible permutation graph on  $2n+3$  vertices encoding the identifier  $\omega$ . The set  $A$ , obtained in step 3 of Algorithm 1, corresponds to the children of  $2n+2$  in the representative tree  $T$  of  $G$ , that is, the vertices  $x_i$  of  $G$ , for  $i = 1, \dots, \ell$ , which are the tail of some tree edge

---

**Algorithm 1**  $decode(G)$ 

---

input: a watermark  $G$  with  $2n + 3$  vertices and up to 2 missing edges

output: the identifier  $\omega$  encoded by  $G$

1. Let  $H$  be the unique Hamiltonian path in  $G$ .
  2. Label the vertices of  $G$  so that  $H$  reads  $2n + 2, 2n + 1, \dots, 0$ .
  3. Let  $A = N_G^-(2n + 2)$ , with  $|A| = \ell$ , and let  $x_1, \dots, x_{\ell-1} \in A$  be the ascending sequence of vertices of  $A \setminus \{2n + 1\}$ .
  4. Return  $\omega = \sum_{i=1}^{\ell-1} 2^{2n-x_i}$ .
- 

of  $G$  pointing to  $2n + 2$ . From Property 8 of canonical reducible permutation graphs, such vertices  $x_i$  which are not  $2n + 1$  are precisely those satisfying  $x_i = n + z_i$ , where  $z_i$  is the index of a digit 1 in the binary representation  $B$  of  $\omega$ . The summation yielding  $\omega$  can now be easily checked, since the relative value of a digit 1 placed at position  $z_i$  is  $2^{n-z_i} = 2^{n-(x_i-n)} = 2^{2n-x_i}$ .

The first step can be accomplished in straightforward fashion. Let  $H$  be initially the single vertex  $v_0 \in V(G)$  whose out-degree is zero. Update  $H$  by concatenating to the left of  $H$  the unique vertex  $v_1$  which is an in-neighbor of  $v_0$  in  $G$ . Now, while  $V(H) \neq V(G)$ , proceed by concatenating to the left of  $H$  the unique vertex  $v_h$ , with  $h = |H|$ , which is an in-neighbor of  $v_{h-1}$  in  $G - \{v_{h-2}, v_{h-3}, \dots, v_0\}$ . The whole process can be easily achieved in linear  $O(|V(G)| + |E(G)|) = O(n)$  time by using adjacency lists for both in-neighbors and out-neighbors of each vertex.

The ascending order, in the third step of the algorithm, can be achieved in linear time by checking in an adjacency matrix whether  $v$  is an in-neighbor of  $2n + 2$ , for each  $v \in \{n + 1, n + 2, \dots, 2n\}$ . Note that it is not necessary to actually obtain the representative tree of  $G$ . Steps 2 and 4 are computed in linear time trivially.  $\square$

## 7 Proofs of the properties from Section 3

We had postponed the proofs of the properties stated in Section 3 to avoid an overhead of technical pages too early in the paper. We now present the full proofs.

**Proof of Property 1** When read from right to left, the  $n$  rightmost elements in  $P_b$  correspond to the  $n$  first elements in  $Z_1$ , i.e the  $n$  first indexes, in  $B^*$ , where a digit 1 is located. Since  $B^*$  starts with a sequence of  $n$  contiguous 1's, the property ensues.  $\square$

**Proof of Property 2** In  $B^*$ , digits with indexes  $1, 2, \dots, n$  are all 1, by construction. Since the  $n$  rightmost elements in  $P_b$  (i.e., elements indexed  $n+2 \leq i \leq n^*$  in  $P_b$ ) correspond to the first  $n$  elements in  $Y$ , and therefore to the first  $n$  indexes of 1's in  $B^*$ , those will always be precisely the elements of set  $S = \{1, 2, \dots, n\}$ . In other words, if  $s \in S$ , then  $s$  will have index  $n^* - s + 1 > n + 1$  in  $P_b$ . By the time the elements of  $P_b$  are gathered together in pairs with views to defining their placement in  $P_s$ , element  $s$  will be paired with element  $q$  whose index is  $n^* - (n^* - s + 1) + 1 = s$ . Because  $s \leq n$ , such  $q$  clearly does not belong to  $S$ , hence  $q > n$ . Now, because  $s$  will be assigned index  $q$  in  $P_s$ , the element with index  $s$  in  $P_s$  will be its pair  $q > n$ , concluding the proof.  $\square$

**Proof of Property 3** The bitonic permutation  $P_b$  is assembled in such a way that its  $(n+1)$ th element  $f = b_{n+1}$  is either:

- (i) the  $(n+1)$ th element of  $Z_0$ , in case  $B^*$  has at least  $n+1$  digits 0; or
- (ii) the  $(n+1)$ th element of  $Z_1$ , otherwise.

By construction, the number of 0's in  $B^*$  is one unit greater than the number of 1's in  $B$ .

If (i) holds, then  $B$  corresponds to an identifier  $w$  that is the predecessor of a power of 2, implying all  $n$  digits of  $B$  are 1's. If that is the case, then the desired property follows immediately, once the  $(n+1)$ th element of  $Z_0$  will be the index of the  $(n+1)$ th — i.e., the last — digit 0 in  $B^*$ . Such index is, by construction,  $n^*$ .

If (ii) holds, then  $f$  is the index of the  $(n+1)$ th digit 1 in  $B^*$ . By construction, the  $n$  first digits 1 in  $B^*$  occupy positions with indexes  $1, \dots, n$ , and the  $(n+1)$ th digit 1 in  $B^*$  corresponds to the first digit 1 in the one's complement of  $B$ . Since that digit has index  $f_0$  in the one's complement of  $B$ , and there are in  $B^*$  exactly  $n$  digits to the left of the one's complement of  $B$ , the property follows.  $\square$

**Proof of Property 4** From the construction of  $P_s$  and Property 1, it follows that the elements that occupy positions with indexes  $1, 2, \dots, n$  in  $P_s$  are the first  $n$  elements in  $P_b$ . It just occurs that the first  $n_1 + 1$  numbers in  $P_b$  are the elements of  $Z_0$ , i.e., the indexes of 0's in  $B^*$ . Now, the last digit in  $B^*$  — the one indexed  $n^*$  — is always a 0. Besides that 0, the other digits 0 in  $B^*$  have indexes  $z = n + d$ , where each  $d$  is the index of a digit 1 in  $B$  (the original binary representation of the identifier  $\omega$ ). While the first digit in  $B$  is always 1, it is also true that:

- (i) the  $f_0 - 1$  first digits in  $B$  constitute a seamless sequence of 1's, in case there is at least one 0 in  $B$ ; or

- (ii) all  $n$  digits of  $B$  are 1's, in which case  $\omega$  is the predecessor of a power of 2.

Whichever the case, Property 3 allows us to state that there is a sequence of  $f - n - 1$  digits 1 in  $B$  starting at the first digit of  $B$ . Such sequence will show up, in  $B^*$ , starting at index  $n + 1$ , in such a way that the  $f - n - 1$  first elements of  $Z_0$  will be  $n + 1, n + 2, \dots, n + (f - n - 1) = f - 1$ . Those elements, as we have seen, will be precisely the first numbers in  $P_b$ . Because there are no more than  $n$  such elements, they will be paired against elements  $1, 2, \dots, f - n - 1 \leq n$  (located from the right end of  $P_b$  leftwards) in order to determine their placement in  $P_s$ , and the property follows.  $\square$

**Proof of Property 5** If the identifier  $\omega$  is not the predecessor of a power of 2, then its binary representation  $B$ , whose first digit is always a 1, contains some digit 0. In light of this, Property 3 implies  $f \geq n + 2$  for all integers  $\omega$ , and the first equality now follows from Property 4. The second equality is granted by the self-invertibility of  $P_s$ , whereby  $s_j = u \iff s_u = j$ .  $\square$

**Proof of Property 6** First, note that  $f \neq n^*$  corresponds to the case where the identifier  $\omega$  is not the predecessor of a power of 2, i.e.,  $n_1 < n$ . Because the sequence  $Z_0$  has exactly  $n_1 + 1$  elements, the last of which being the index  $n^*$  of the rightmost digit in  $B^*$ , element  $n^*$  will always be assigned index  $n_1 + 1$  in  $P_b$ . As we have seen in the proof of Property 4, for  $i \leq n$ , the  $i$ th element in  $P_b$  will also be the  $i$ th element in  $P_s$ , for it will be paired against element  $i$ , indexed  $n^* - i + 1$  in  $P_b$  (due to the starting sequence of  $n$  digits 1 in  $B^*$ ). That being said, element  $n^*$ , indexed  $n_1 + 1 \leq n$  in  $P_b$ , will have index  $n_1 + 1$  in  $P_s$  as well. If  $f = n^*$ , then the definition of  $f$  verifies the property trivially.  $\square$

**Proof of Property 7** We employ again the fact, noted for the first time in the proof of Property 4, that the subsequence consisting of the first  $n$  elements in  $P_s$  and the subsequence consisting of the first  $n$  elements in  $P_b$  are one and the same. Since  $P_b$  is bitonic, whatever subsequence of  $P_b$  is bitonic too, particularly the one containing its first  $n$  elements. By Property 5, the central element  $s_{n+1}$  of  $P_s$  is always equal to 1, therefore the bitonic property of the subsequence consisting of the leftmost elements of  $P_s$  will not be broken after its length has grown from  $n$  to  $n + 1$ , that is, after element  $s_{n+1} = 1$  has been appended to it.  $\square$

**Proof of Property 8** The first  $n_1 + 1$  elements of the bitonic permutation  $P_b$  are the elements of  $Z_0$ , corresponding to the indexes of 0's in the extended binary  $B^*$  (which consists, we recall, of  $n$  digits 1, followed by the one's complement of the binary representation  $B$  of the identifier  $\omega$  encoded by  $G$ , followed by a single digit 0). Those elements constitute the ascending prefix  $A = n + z_1, n + z_2, \dots, n + z_{n_1}, 2n + 1$ , where, for  $i \in \{1, \dots, n_1\}$ ,  $z_i$  is the index of a digit 1 in  $B$ . From the proof of Property 4, we know that, for  $i \leq n$ , the  $i$ th element in  $P_b$  will also be the  $i$ th element in the self-inverting permutation  $P_s$ . Since  $n_1 \leq n$ , we have that the  $n_1$  first elements of  $P_s$  are precisely the  $n_1$  first elements of  $A$ , hence the tree edge tailed at each of those elements must point, by construction, to  $2n + 2$ . It remains to show that no element  $u \notin A \cup \{2n + 1\}$  is the tail of a tree edge pointing to  $2n + 2$ . But this comes easily from the fact that, by Property 6, the  $(n_1 + 1)$ th element in  $P_s$  is  $2n + 1$ . Since all vertices  $u$  with indexes  $i > n_1 + 1$  in  $P_s$  are certainly smaller than  $2n + 1$ , they can only be the tail of tree edges pointing to vertices  $q(u) \leq 2n + 1$ , and the proof is complete.  $\square$

**Proof of Property 9** Both items are trivially verified, since, by construction, every tree edge  $(u, k) \in G$  is such that either  $k > u$  is the element that is closest to  $u$  and to the left of  $u$  in  $P_s$ , or  $k = 2n + 2$ .  $\square$

## 8 Final considerations

We characterized the class of canonical reducible permutation graphs devised by Chroni and Nikolopoulos in [4]. Such graphs allow for the encoding of binary identifiers and can be embedded into control-flow graphs of software through the insertion of dummy code.

Our characterization led to a simpler linear-time decoding algorithm and a polynomial-time algorithm to retrieve the encoded word from a damaged graph (with a constant number  $k$  of missing edges). Note that an attacker will probably not know where the watermark is located (otherwise the watermark itself could be removed altogether). The more edges that are arbitrarily chosen to be removed, the higher the probability that an edge that *does not* belong to the watermark is removed and the program itself gets damaged. It is therefore reasonable to regard  $k$  as a small constant for all practical purposes whenever it is possible to do so deterministically.

The proposed characterization actually gives rise to a linear-time algorithm which can always detect an attack *and restore* the original graph when  $k \leq 2$  edges are missing. It can also detect (without restoring the graph) that  $k$  edge removals and/or insertions were done, for  $3 \leq k \leq 5$ . Such results are presented—and shown to be the best possible—in [2], where fur-

ther details about the resilience of canonical reducible permutation graphs against this sort of attack are given.

An interesting open question is whether the problem is fixed-parameter tractable with respect to  $k$ . Another question is whether it is possible to cope with the graph editing problem in its full generality.
